**Abstract.** This paper describes the results obtained in the design and characterization of a tubular electrochemical reactor. The set-up was employed for on-site hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) production in an acidic medium (pH 3) to promote three electrochemical advanced oxidation processes (EAOP): electro-Fenton (EF), photoelectro-Fenton (PEF) and photocatalysis treatment (PT). These processes were evaluated by their abilities to degrade a commercial dye, Orange-II (OG-II), in solution using total organic carbon (TOC) removal and high performance liquid chromatography (HPLC). To have free solutions of iron in the EF and PEF systems, a Nafion™ membrane with dispersed iron was prepared. For use in photocatalysis, electrodes with a large superficial area were prepared by coating carbon cloth fiber supports with titanium dioxide (TiO<sub>2</sub>) using the electrophoretic (EP) method. In this work, wastewater samples with a large number of microorganisms (coliform bacteria) were treated with this new reactor design.

**Key Words:** Electro-Fenton, Photoelectro-Fenton, Hydrogen peroxide, Photoelectrochemistry, Electrochemical reactor, Disinfection.

**Resumen.** En este trabajo se describen los resultados obtenidos en el diseño y la caracterización de un reactor electroquímico tubular. Dicho reactor se usó para llevar a cabo la producción in situ de peróxido de hidrógeno (H<sub>2</sub>O<sub>2</sub>) en medio ácido (pH 3) para promover tres procesos electroquímicos de oxidación avanzada (PEOA): electro-Fenton (EF), fotoelectro-Fenton (FEF) y fotocatalisis (FC). Estos procesos fueron evaluados por su capacidad para degradar un colorante comercial, Naranja-II (N-II), en solución. Para ello, se realizaron determinaciones de carbono orgánico total (COT) así como de cromatografía líquida de alta resolución (CLAR). Para tener soluciones libres de hierro en los procesos EF y FEF, se preparó una membrana Nafion<sup>R</sup> con hierro disperso. Para las pruebas fotocatalíticas se desarrollaron electrodos con una gran área superficial que se prepararon mediante el recubrimiento con dióxido de titanio (TiO<sub>2</sub>) de una tela de fibra de carbono usando el método electroforético (ME). Además se trabajó con muestras de agua residual con un gran número de microorganismos (bacterias coliformes) la cual fue tratada con este nuevo diseño de reactor.

**Palabras clave:** Electro-Fenton, fotoelectro-Fenton, peróxido de hidrógeno, fotoelectroquímica, reactor electroquímico, Desinfección.

## Introduction

Hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) is currently one of the most common chemicals used for water treatment and chemical production, and it is a promising oxidant for green chemistry processes in the near future [1,2,3]. The use of H<sub>2</sub>O<sub>2</sub> may offer an efficient alternative for controlling pollution in aqueous media. Hydrogen peroxide is one of the most popular non-selective oxidizing agents that are used to convert organic compounds to carbon dioxide and water [4]. Recently, several works have demonstrated that on-site electrochemical generation of H<sub>2</sub>O<sub>2</sub> can be used successfully to decontaminate water treatment effluents with different organic compounds [5-8]. In this process, H<sub>2</sub>O<sub>2</sub> is continuously supplied to the contaminated solution through oxygen (O<sub>2</sub>) reduction by two electrons in an acidic medium, according to the following equation [9-12]:

The most common use of H<sub>2</sub>O<sub>2</sub> in environmental applications involves the addition of iron (Fe<sup>2+</sup>) to the acidic solution to increase the oxidizing power of the H<sub>2</sub>O<sub>2</sub> by forming hydroxyl radicals (•OH) via the Fenton reaction, according to the equation [13,14].

This method is commonly referred to as electro-Fenton (EF) treatment and is considered an advanced oxidation process (AOP) [15]. The principal reason for combining on-site hydrogen peroxide generation and the Fenton reaction is to improve the oxidation capacities of the two individual processes, creating a synergetic system [16]. The hydroxyl radical species that are produced through these processes are characterized by a large oxidation power (2.8 V vs ENH) [17] that is able to transform organic compounds into CO<sub>2</sub> and H<sub>2</sub>O [18].

Similarly, another type of AOP is the photoelectro-Fenton (PEF) system, in which the peroxide-ferrous system is illuminated with UV light, and Reactions 3 and 4 take place in addition to Equation 2, increasing the production of hydroxyl radicals and improving the oxidation of organic compounds [19].

This catalytic process is achieved by Fe<sup>2+</sup> regeneration, which takes place primarily by the reduction of Fe<sup>2+</sup> species

by  $\text{H}_2\text{O}_2$ . When UV light is used, the mineralization process can be accelerated by the photolysis of complexes of  $\text{Fe}^{3+}$  with some oxidation products and improvement in  $\text{Fe}^{2+}$  regeneration from the additional photoreduction of  $\text{Fe}^{3+}$  species through Equation 4 [19].

In the case of the EF and PEF systems, the iron species represent a serious problem during organic compound oxidation in a homogeneous medium. The removal of iron ions is an easy process that can be carried out by precipitation or re-dissolution of the iron ions after the treatment, but these operations generate additional costs in the treatment [20].

However, in the recent years, the use of Nafion™ membranes covered with highly dispersed iron ions has been the focus of several studies because the iron-coated Nafion™ membrane has a similar effect on  $\text{H}_2\text{O}_2$  decomposition as the iron ions in a homogeneous solution [20, 21,22]. The iron ions that are supported on the membrane allow the oxidation of the organic compounds through UV irradiation while avoiding the need for an expensive separation step [20].

In addition to the Fenton-related technologies, the photocatalytic process has become a commonly used technology because it can completely remove organic compounds [23]. Titanium dioxide ( $\text{TiO}_2$ ) is the most common semiconductor material for photocatalytic processes, and it has been applied in several photocatalytic water treatment studies [24,25]. The inherent advantages of this material are its low cost, its low toxicity, its good photocatalytic properties, and its particularly wide band gap (3.2 eV), which results in good stability and prevents photo-corrosion [26]. When  $\text{TiO}_2$  nanoparticles are subjected to radiation with sufficient energy, an electron is promoted from the valence band to the conduction band of the semiconductor, as indicated in Equation 5:

The positively charged vacancy or hole ( $h^+$ ) thus generated can react with either adsorbed water or hydroxyl ions to produce the powerful  $\bullet\text{OH}$  radical, as shown in Equations 6 and 7.

Furthermore, if an organic pollutant, R, is adsorbed on the semiconductor surface, the hole can directly oxidize that species, as outlined in Equation 8 [27].

At the same time, the electrons that are photo-injected into the conduction band can react with dissolved  $\text{O}_2$  to produce  $\text{H}_2\text{O}_2$ , according to Equation 1, or they may be lost by recombination reactions with either unreached holes or with adsorbed  $\bullet\text{OH}$  radicals, as indicated in Equations 9 and 10, respectively [28].

If the semiconductor is used as an anode, those electrons can be extracted to the external circuit, retarding Equations 9 and 10.

Because  $\text{TiO}_2$  is a suspended powder, the reactor design should be efficient to avoid problems related to illumination limitations, mass transfer and nanoparticle recovery at the end of the treatment process [29,30]. One promising way to overcome such problems is to immobilize the catalyst [11,29]. In this method, mass transfer limitations are reduced by using microfibers as a direct support for the  $\text{TiO}_2$ , and the illumination source is placed directly over the  $\text{TiO}_2$ -covered face of the support.

The aim of this work is to compare the effectiveness of several of these water-treatment processes by studying the degradation of the azo dye Orange-II (OG-II) using high performance liquid chromatography (HPLC) and total organic carbon (TOC) analysis on water containing microorganisms. Tests were carried out using a continuous flow reactor that was operated to produce on-site  $\text{H}_2\text{O}_2$  using the EF and the PEF processes. In addition, a Nafion™ membrane with iron fixed in the lattice and a  $\text{TiO}_2$ -covered carbon cloth were incorporated to promote photocatalytic events and improve the oxidation of the organic compounds and microorganisms in the medium.

## Experimental details

The chemicals used in this work, such as sulfuric acid ( $\text{H}_2\text{SO}_4$ ), sodium sulfate ( $\text{Na}_2\text{SO}_4$ ), and ferrous sulfate ( $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ ), were purchased from J.T. Baker as ACS reagent grade and were used as received, without further purification. Titanium (IV) oxysulfate ( $\text{TiOSO}_4$ , 99.99%, ca. 15 wt. diluted sulfuric acid solution) and the azo dye OG II ( $\text{C}_{16}\text{H}_{11}\text{N}_2\text{NaO}_4\text{S}$ ,  $\lambda_{\text{max}} = 487 \text{ nm}$ , reagent grade) were purchased from Sigma-Aldrich. The carbon cloth and Nafion™ membrane were provided by ElectroChem Inc.

## Electrochemical photo-reactor

The experiments were performed in an annular flow reactor containing a graphite cloth cathode (geometrical area of  $90 \text{ cm}^2$ ) and a  $\text{TiO}_2$ -covered graphite cloth anode (geometrical area of  $100 \text{ cm}^2$ ), as shown in Figure 1. Additional studies are being carried out using the same reactor design with minor modifications in the capacity and anode materials [15].

The reactor volume was 0.5 L, and the total solution volume, including that held in a reservoir stirred and sparged with pure  $\text{O}_2$ , was 27 L. In this set-up, a diaphragm pump (Shurflo) was used to create three flow rates, 56 L/h, 76 L/h and 96 L/h. Prior to the Fenton-reagent oxidation tests, a ferrous sulfate solution was added to make an  $\text{Fe}^{2+}$  concentration of either 0.02

**Figure 1.** Diagram of the experimental photo-electrochemical reactor. 1) Deposit, 2) Inlet chamber, 3) Carbon cloth cathode, 4) Photo-chamber, 5) UV lamp, 6) Power supply, 7) UV lamp power supply, 8) TiO<sub>2</sub>-carbon cloth anode, 9) Outlet chamber, 10) Nafion™ membrane with dispersed Fe<sup>2+</sup>, 11) Deposit exit, 12) Oxygen supply, 13) Pump.

or 0.05 mM. In the photo-assisted experiments, the illumination was provided by a low-pressure UV mercury lamp (UVP Inc.,  $P = 75 \text{ mW/cm}^2$ ,  $\lambda = 365 \text{ nm}$ ). The assays were carried out under galvanostatic conditions with a GW Model:GPR-1820HD power supply.

### Evaluation of on-site H<sub>2</sub>O<sub>2</sub> production

Electrolysis experiments were carried out to test the capacity of the reactor to produce H<sub>2</sub>O<sub>2</sub> through the cathodic reduction of dissolved O<sub>2</sub> in a 0.05 M solution of Na<sub>2</sub>SO<sub>4</sub>, adjusted to a pH of 3 with H<sub>2</sub>SO<sub>4</sub> and saturated with O<sub>2</sub>. The pH of the solution was determined with a glass-electrode pH meter (Corning 320). The concentration of H<sub>2</sub>O<sub>2</sub> created during electrolysis was determined by titrating with titanium (IV) oxysulfate and measuring the intensity of the color of the H<sub>2</sub>O<sub>2</sub>-reagent complex at a wavelength of 406 nm [31].

### OG-II solution preparation

An accurately weighed quantity of the OG-II dye was dissolved in distilled water to prepare a stock solution (100 mg/L), and experimental solutions of the desired concentration (50 mg/L) were obtained by successive dilution. The synthetic textile dye wastewater solution was prepared in accordance with previous reports [28] in which dye concentrations ranging between 10 and 200 mg/L.

### Analytical procedure

The degradation of OG-II was monitored by HPLC analysis, using a Hewlett Packard Series 1050 machine, equipped with a UV/Vis Detector and a reverse phase C-18 Phenomenex (LUNA 5 micron-C-18, 3 x 150 mm) column. The injection volume was 20  $\mu\text{L}$ . The column was eluted with an ammonium acetate (20 mM)/acetonitrile 68:32 (v/v) mixture with a flow

rate of 0.5 mL/min [24]. The TOC of the initial electrolyzed samples was determined with a TOC-VSCN (Shimadzu Co) analyzer.

### Nafion™ membrane preparation

The Nafion™ membrane (EC-NM-117) was exchanged with FeCl<sub>3</sub>·6H<sub>2</sub>O (Fluka) at room temperature for a few minutes, after which the Nafion™ was immersed in HCl. After the ion exchange, the membrane was washed with water and then immersed in 1 M NaOH to hydrate the Fe<sup>3+</sup> ions, in accordance with Fernandez et al. [21]. For the TiO<sub>2</sub>-covered carbon cloth electrodes, nano-particulated P25 TiO<sub>2</sub> (80% anatase, 20% rutile, average particle diameter 20 nm), purchased from Degussa was used. The nanoparticles were deposited according to the methodology proposed by Manríquez and Godínez [32]. Scanning electron microscopy (SEM) of the TiO<sub>2</sub> electrode surfaces was carried out using a JEOL-5400LV microscope.

## Results and discussion

### Electrochemical generation of H<sub>2</sub>O<sub>2</sub> in the photo-reactor at different flow rates

Several tests were performed to evaluate the electrochemically generated H<sub>2</sub>O<sub>2</sub> concentration in the reactor at different current densities ( $j$ ) and flow rates ( $Q$ ). The capacity of the system to electrochemically generate H<sub>2</sub>O<sub>2</sub> at the carbon cloth cathode through O<sub>2</sub> reduction (Eq. 1) was studied spectrophotometrically. Figure 2 shows the variation of the H<sub>2</sub>O<sub>2</sub> concentration as a function of the electrolysis time and current densities with a flow rate of 56 L/h. Curve 2(A) corresponds to a sample in which the current density was 100 mA/cm<sup>2</sup>; in this case, the H<sub>2</sub>O<sub>2</sub> concentration was approximately 39 mg/L after a reaction time of 180 min. Curve 2(B) corresponds to a current density of 200 mA/cm<sup>2</sup>, and the resulting H<sub>2</sub>O<sub>2</sub> accumulation was approximately 89 mg/L after 180 min of electrolysis. Finally,

**Figure 2.** H<sub>2</sub>O<sub>2</sub> production in the photo-electrochemical reactor in a solution of 0.05 M Na<sub>2</sub>SO<sub>4</sub>, with a flow rate of 56 L/h and a current density of (A) 100 mA/cm<sup>2</sup>, (B) 200 mA/cm<sup>2</sup>, (C) 300 mA/cm<sup>2</sup>.

curve 2(C) shows a current density of 300 mA/cm<sup>2</sup>, which resulted in 133 mg/L H<sub>2</sub>O<sub>2</sub>.

In all cases, it can be seen that the H<sub>2</sub>O<sub>2</sub> concentration is directly proportional to the current density supplied to the system. On the other hand, the H<sub>2</sub>O<sub>2</sub> concentration did not increase linearly with reaction time; after about 80 min, the H<sub>2</sub>O<sub>2</sub> concentration reached its plateau value and remained almost constant for the remainder of the reaction time. These results are in accordance with previously reported [33]. From these results, it is apparent that H<sub>2</sub>O<sub>2</sub> undergoes chemical decomposition O<sub>2</sub> either on the anode (heterogeneous process) or in the medium (homogeneous process) [34,35]:

An additional set of assays was carried out in which the flow rate was increased to 76 L/h, and the three current densities used in the previous assay were maintained. The results of this study are presented in Figure 3. In these experiments, H<sub>2</sub>O<sub>2</sub> generation is favored by the increased flow rate. The H<sub>2</sub>O<sub>2</sub> concentration was 75 mg/L after 180 min of reaction when a current density of 100 mA/cm<sup>2</sup> was applied, 166 mg/L when a current density of 200 mA/cm<sup>2</sup> was applied, 268 mg/L when a current density of 300 mA/cm<sup>2</sup> was applied. In this last case, the maximal H<sub>2</sub>O<sub>2</sub> concentration is larger than what was obtained with the same current density at the lower flow rate (Figure 2(C)).

To improve the efficiency of H<sub>2</sub>O<sub>2</sub> generation, an additional flow rate of 96 L/h was tested using the same three current densities as before. The results are presented in Figure 4. As in the previous tests, for current densities of 100 mA/cm<sup>2</sup> and 200 mA/cm<sup>2</sup>, the H<sub>2</sub>O<sub>2</sub> concentration is directly proportional to the applied charge, generating 54 mg/L (curve 4(A)) and 104 mg/L (curve 4(B)) after 180 min of reaction, respectively. However, when the current density was 300 mA/cm<sup>2</sup> (curve 4(C)), the H<sub>2</sub>O<sub>2</sub> concentration is drastically decreased relative to concentration obtained with the lower current densities. The maximal accumulation is approximately 95 mg/L after 180 min

**Figure 3.** H<sub>2</sub>O<sub>2</sub> production in the photo-electrochemical reactor in a solution of 0.05 M Na<sub>2</sub>SO<sub>4</sub> with a flow rate of 76 L/h. The current densities were (A) 100 mA/cm<sup>2</sup>, (B) 200 mA/cm<sup>2</sup> and (C) 300 mA/cm<sup>2</sup>.

**Figure 4.** H<sub>2</sub>O<sub>2</sub> production in the photo-electrochemical reactor in a solution of 0.05 M Na<sub>2</sub>SO<sub>4</sub> with a flow rate of 96 L/h. The current densities were (A) 100 mA/cm<sup>2</sup>, (B) 200 mA/cm<sup>2</sup> and (C) 300 mA/cm<sup>2</sup>.

of reaction, a value that is smaller than what was obtained with a current density of 200 mA/cm<sup>2</sup>. A possible explanation for this phenomenon is the mass transfer coefficient of the H<sub>2</sub>O<sub>2</sub> formation in the system.

The shape of the curves can be explained by considering the gradual accumulation of H<sub>2</sub>O<sub>2</sub> that must be associated with its proportional decomposition in a complex process that probably includes both homogeneous and heterogeneous reactions. Equation 13 for instance, shows that although the rate of H<sub>2</sub>O<sub>2</sub> production depends on the interfacial activity of the O<sub>2</sub> at the cathode and on the corresponding electrode transfer rate constant,  $k_1$ , decomposition can be assumed to depend on heterogeneous and homogeneous processes taking place at both the anode and the cathode. In this way, the combined decomposition rate is a function of the corresponding rate constants,  $k_2$ ,  $k_3$ ,  $k_4$  and  $k_5$  ( $k_2$  and  $k_4$  for homogeneous and  $k_3$  and  $k_5$  for heterogeneous processes) and of the local activity of H<sub>2</sub>O<sub>2</sub> at either the cathode or the anode ( $[\text{H}_2\text{O}_2]_{0,c}$  and  $[\text{H}_2\text{O}_2]_{0,a}$ , respectively).

$$\frac{d[\text{H}_2\text{O}_2]_0}{dt} = k_1[\text{O}_2]_{0,c} - k_2[\text{H}_2\text{O}_2]_{f,c} - k_3[\text{H}_2\text{O}_2]_{0,c} - k_4[\text{H}_2\text{O}_2]_{f,a} - k_5[\text{H}_2\text{O}_2]_{0,a} \quad (13)$$

The activities of the compounds in the interfacial electrode solution in Equation 13 ( $[\text{O}_2]_{0,c}$ ,  $[\text{H}_2\text{O}_2]_{0,c}$  and  $[\text{H}_2\text{O}_2]_{0,a}$ ) can be associated with those in the bulk solution ( $[\text{O}_2]_{sol}$  and  $[\text{H}_2\text{O}_2]_{sol}$ ) by assuming a linear relationship between the two activity values through a mass transfer-related constant, which allows factorization and reduction of Equation 13 to Equation 14, in which two new constants,  $k'$  and  $k''$ , contain information on the kinetic and mass transport properties of the system.

$$\frac{d[\text{H}_2\text{O}_2]_{sol}}{dt} = k'[\text{O}_2]_{sol} - k''[\text{H}_2\text{O}_2]_{sol} \quad (14)$$

Evaluation of this differential equation results in Equation 15, which demonstrates that the concentration of H<sub>2</sub>O<sub>2</sub> in the

bulk solution follows an exponential relationship with time, which describes the behavior of each of the curves.

$$[\text{H}_2\text{O}_2]_{\text{sol}} = \left( \frac{k'[\text{O}_2]_{\text{sol}}}{k''} \right) (1 - e^{-k''t}) \quad (15)$$

We applied Equations 13 to 15 to the results from the experiment with a flow rate of 76 L/h because this experiment shows a definite tendency than those with flow rates of 56 L/h and 96 L/h. The corresponding adjustments are shown in Figure 5, and the resulting values of  $k'$  and  $k''$  are presented in Table 1.

The results presented in Table 1 demonstrate that the greatest  $\text{H}_2\text{O}_2$  production takes place when a current density of 300 mA/cm<sup>2</sup> and a flow rate of 76 L/h are applied. Under these conditions,  $k''$  is greater than  $k'$ , and therefore the decomposition of  $\text{H}_2\text{O}_2$  is inhibited.

At very long reaction times, Equation 15 predicts that the concentration of  $\text{H}_2\text{O}_2$  loses its dependence on time (as shown in Equation 16), reaching a constant value that depends only on the constants,  $k'$  and  $k''$ , and the concentration of dissolved  $\text{O}_2$  in the electrolytic medium.

$$[\text{H}_2\text{O}_2]_{\text{sol}} = \lim_{t \rightarrow \infty} \frac{k'[\text{O}_2]_{\text{sol}}}{k''} \quad (16)$$

This preliminary model predicts that operating under mass transfer conditions of the electrochemical reactor controls the limiting concentration of  $\text{H}_2\text{O}_2$  that can be produced because the concentration of  $\text{O}_2$  in the medium is saturated and can be assumed to be constant.

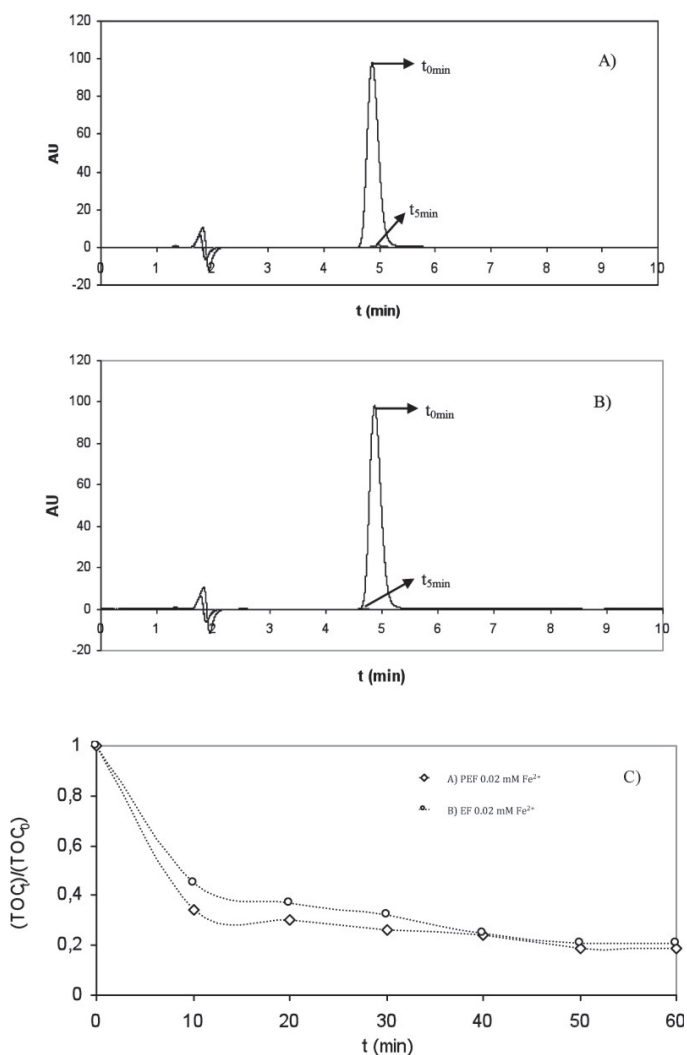

**Figure 5.** Simulated values obtained with a flow rate of 76 L/h and current densities of (A) 100 mA/cm<sup>2</sup>, (B) 200 mA/cm<sup>2</sup>, and (C) 300 mA/cm<sup>2</sup>.

## Degradation of OG-II by the EF and PEF processes

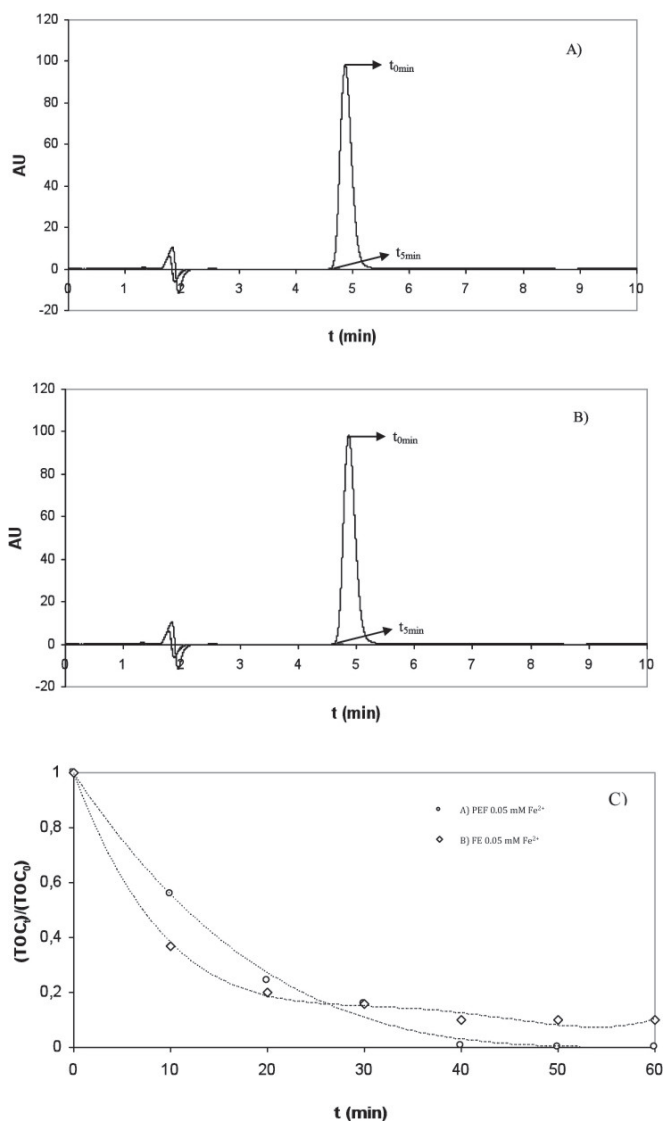

Studies of OG-II oxidation by electrically generated  $\text{H}_2\text{O}_2$  were carried out with a current density of 300 mA/cm<sup>2</sup> and a flow rate of 76 L/h. In these experiments, two  $\text{Fe}^{2+}$  concentrations, 0.02 mM and 0.05 mM, in a total volume of 27 L were used. In both cases, the process started with an initial  $\text{H}_2\text{O}_2$  concentration of 250 mg/L. Figure 6(A) shows the HPLC analysis of a solution containing 50 mg/L of OG-II treated with the EF system with a  $\text{Fe}^{2+}$  concentration of 0.02 mM, and Figure 6(B) shows the results for the PEF process under the same conditions. The results show that both the EF and PEF systems completely decolorize the OG-II system after 5 min of treatment, indicating that both are very effective for removing organic compound OG-II.

**Figure 6.** Degradation of 50 mg/L OG-II dye with the (a) EF assay and (b) PEF assay,  $[\text{H}_2\text{O}_2]_0 = 250$  mg/L with 0.02 mM  $\text{Fe}^{2+}$  at different sampling times, measured under the following conditions:  $\lambda = 487$  nm, mobile phase:  $\text{ACNH}_4$  68%, ACN 32% and flow rate = 0.5 mL/min. (c) TOC removal in the 50 mg/L OG-II dye solution in the (i) PEF system and (ii) EF system,  $[\text{H}_2\text{O}_2] = 250$  mg/L, 0.02 mM  $\text{Fe}^{2+}$ , pH = 3, volume = 27 L, flow rate = 76 L/h, current density = 300 mA/cm<sup>2</sup>.

Figure 6(C) shows TOC removal as a function of time for both the EF and PEF systems. With an  $\text{Fe}^{2+}$  concentration of 0.02 mM, the mineralization level of the OG-II dye was approximately 80% after 60 min of treatment with either the EF or PEF system. This phenomenon is caused by the photo-reduction of  $\text{Fe}(\text{OH})^{2+}$  complexes to  $\text{Fe}^{2+}$ , which increases the production of  $\bullet\text{OH}$  oxidant species in the medium, in accordance with Equation 4.

To estimate the effect of the  $\text{Fe}^{2+}$  concentration on the removal of the OG-II dye, a greater  $\text{Fe}^{2+}$  concentration (0.05 mM) was tested in a similar manner using both the EF and PEF systems. The results of these experiments are presented in Figure 7.

**Figure 7.** Degradation of 50 mg/L OG-II dye with the (a) EF assay and (b) PEF assay,  $[\text{H}_2\text{O}_2]_0 = 250$  mg/L and 0.05 mM  $\text{Fe}^{2+}$  at different sampling times, measured under the following conditions:  $\lambda = 487$  nm, mobile phase:  $\text{ACNH}_4$  68%, ACN 32% and flow rate 0.5 mL/min. (c) TOC removal in the 50 mg/L OG-II dye solution in the (i) PEF system and (ii) EF system,  $[\text{H}_2\text{O}_2] = 250$  mg/L, 0.05 mM  $\text{Fe}^{2+}$ , pH = 3, volume = 27 L, flow rate = 76 L/h, current density = 300 mA/cm<sup>2</sup>.

The HPLC analysis of the OG-II dye dissolution carried out with an  $\text{Fe}^{2+}$  concentration of 0.05 mM by EF and PEF is shown in Figures 7(A) and 7(B), respectively. For each method, samples were collected at a number of time points during the experiment for quantification of OG-II dye presence by HPLC. Again, it is evident that the oxidation of the OG-II dye using either the EF or the PEF process is efficient because the color is removed, as seen by the decrease in signal at a wavelength of 487 nm.

To measure the mineralization by these two processes of the OG-II dye, analysis of TOC was carried out. The results are shown in Figure 7(C). When the  $\text{Fe}^{2+}$  concentration was 0.05 mM, the mineralization of the OG-II dye is improved compared to the lower  $\text{Fe}^{2+}$  concentration (0.02 mM), with TOC removal close to 90% for the EF system and 100% for the PEF process after 60 min of treatment.

#### *Incorporation of a Nafion™ membrane with an immobilized iron catalyst in the photo-electrochemical reactor*

In this part of the work, a Nafion™ membrane was incorporated into the system to avoid the need for  $\text{Fe}^{2+}$  addition to the solution and to promote photo-assisted processes that can be used to mineralize pollutants. In Figure 8, we show a SEM image of a membrane that was prepared by the method of Kiwi et al. [20-22]. Figure 8(A) shows the membrane without  $\text{Fe}^{2+}$  in the lattice, and Figure 8(B) shows the membrane with  $\text{Fe}^{2+}$ . It is clear that the dispersion of  $\text{Fe}^{2+}$  over the membrane lattice is homogeneous and is in the form of clusters. The  $\text{Fe}^{2+}$  fixed in the Nafion™ membrane is excited by UV light, forming  $\bullet\text{OH}$  radicals via  $\text{H}_2\text{O}_2$  decomposition [22].

#### *Incorporation of carbon fibers coated with $\text{TiO}_2$ films in the photo-electrochemical reactor*

A new innovation of this photo-electrochemical reactor is the incorporation of  $\text{TiO}_2$  electrodes to promote photocatalytic phenomena to improve organic compound removal [36]. Figure 9 shows the SEM images of the  $\text{TiO}_2$ -carbon cloth electrodes that were prepared by electrophoretic deposition. As shown in Figure 9(A), the  $\text{TiO}_2$  deposits (40 s deposition time) were not completely homogeneous, and in some places, the surface of the uncoated carbon cloth can be observed. However, when the electrophoretic deposition time was increased to 60 s, the

**Figure 8.** SEM images of (a) a Nafion™ membrane without  $\text{Fe}^{2+}$  and (b) a Nafion™ membrane with  $\text{Fe}^{2+}$  clusters in the lattice.

**Figure 9.** SEM images of carbon cloth fibers coated with TiO<sub>2</sub>. (a) Deposition time of 40 s, T = 450 °C for 30 min. (b) Deposition time of 60 s, T = 450 °C for 30 min.

coverage was uniform over the carbon cloth lattice, as shown in Figure 9(B).

*Removal of coliforms in the photo-electrochemical reactor using a Nafion™ membrane with dispersed iron, TiO<sub>2</sub>-carbon cloth electrode and continuous H<sub>2</sub>O<sub>2</sub> electrogeneration*

To evaluate the capacity of the new photo-electrochemical reactor to remove coliforms from an effluent stream, several tests were performed with wastewater supplied from a municipal network. The experiment was carried out in the presence of H<sub>2</sub>O<sub>2</sub> that was continuously electro-generated in the system with an Fe<sup>2+</sup>-fixed Nafion™ membrane and a TiO<sub>2</sub>-carbon cloth anode. The system was continuously illuminated to promote the photo-oxidation process. Figure 10 shows the coliform removal, reported with a presumptive water quality test, through determination of the most probable number (NMP) of total coliforms, fecal coliforms (thermal tolerants), and *Escherichia coli*. The new photo-electrochemical reactor removes 100% of the coliforms after 10 min of the oxidation process, indicating that the reactor is efficient in the removal of organic material in aqueous effluents.

These results are in accordance with reported recently by S.N. Hussain, et al [37], where these authors carry out disinfection

**Figure 10.** Abatement of total coliforms with time using the PEF system with an Fe<sup>2+</sup>-coated Nafion™ membrane and a TiO<sub>2</sub>-carbon cloth electrode.

performance of a unique process of adsorption combined with electrochemical treatment.

## Conclusions

The carbon cloth is an efficient material for O<sub>2</sub> reduction and H<sub>2</sub>O<sub>2</sub> formation. In this new photo-electrochemical reactor, the production of H<sub>2</sub>O<sub>2</sub> reaches 260 mg/L. Using dimensionless groups, we developed a general equation to scale-up the photo-electrochemical reactor. In the AOPs, the best Fe<sup>2+</sup> concentration was 0.05 mM, resulting in 90% color removal of the OG-II dye. With the incorporation of a Fe<sup>2+</sup>-fixed Nafion™ membrane and a TiO<sub>2</sub>-carbon cloth anode, the system performs better than without these additions, with a measured coliform bacteria removal ability of 100%.

## Acknowledgments

The authors wish to thank the CONACyT for financial support this research.
